

1 Introduction

One widely used model of concurrency is Javascript's Promises. A promise works in some ways like a lazy value, in that it will at some point will contain the result of a computation, but does not stop flow of control in the current thread to compute that value. Unlike a value with lazy semantics, a promise can immediately begin computation in a separate thread as opposed to waiting for the result to be requested by some other computation.

Promises are composable: using `then` and `catch`, we can chain a promise onto the end of a different one creating a new promise that continues computation after the first has succeeded or failed respectively.

We build a model of promises in Haskell to compare it against other concurrency frameworks.

2 Motivation

[Discussion of the adoption of the promises model in Javascript; will have to see what I can find citations for.]

Promise objects are a good candidate for parameterized types: they yield a value upon success or failure, and it would be nice to be able to check statically that these values and the functions that they will be passed to all agree on the types involved.

The operation then should "chain promises together" by accepting a function that converts a regular value to a promise, then applying it to a promise with that return type by waiting for it to finish before calling the function. We note that this operation is very similar to `>>=` [give type signature here?], suggesting that promises can be thought of as monads. (We also note that it is trivial to wrap an arbitrary value into a promise so `return` poses no problem. In practice, we define a separate constructor for this case to avoid forking off an entire new thread to do no computation and hand back the same result immediately.)

3 Background

[description of MVar] [maybe discuss GADTs briefly ?]

[Terminology for discussing promises: states *pending*, *fulfilled*, *rejected*; `resolve` means `pending` -> `fulfilled`, `reject` - `pending` -> `rejected`, `settle` - `pending` -> `<either>`; define promise chain; Promises here \neq lazy values, despite terminology clash w/ e.g. Scheme]

4 Haskell Implementation

[core bits] Javascript's `Promise()` constructor builds a new promise object from an 'executor' function. The executor accepts two callback functions the standard names `resolutionFunc` and `rejectionFunc`, one to call in the case of successful resolution and the other for failure. The executor will, on a success/failure, call `resolutionFunc/rejectionFunc`, respectively, passing in the value of or reason for the success or failure. Let's assume we want a promise with type `Promise f p`, i.e. one where success results in a value of type `p` and failure gives a reason with type `f`. To build one, `resolutionFunc` will need to accept a value of type `p`. Since calling `resolutionFunc` will settle the promise and therefore have effects elsewhere in the promise chain, its return type will have to be something wrapped in `IO`, so we know `resolutionFunc :: p -> IO ?`. Similarly, `rejectionFunc` must accept a `f`, and calling it will also settle the promise, so `rejectionFunc :: f -> IO ?`. The executor function should accept `resolutionFunc` and `rejectionFunc` as parameters and is expected to end by calling exactly one of them, so we will expect it to have a proper tail call to one of the parameters. This means its return type matches that of `resolutionFunc` and `rejectionFunc`, i.e. `executor :: (p -> IO ?) -> (f -> IO ?) -> IO ?` and the `?s` for the two callbacks should be the same type. [For now, let's use `()` as `?`, so that the callbacks have a return type of `IO ()`, the conventional Haskell type for `IO` actions that have an effect (here, setting the `Promise` from `Pending` state to one of the settled states) instead of containing a useful value.] Our function for building a `Promise` object needs to accept a function with the type of executor and give back a `Promise` value, which must be contained in `IO` because it has the side effect of running the executor in another thread. It thus has the type `newPromise :: ((p -> IO ()) -> (f -> IO ())) -> IO (Promise f p)`. We can represent a `Promise f p` by an `MVar (Either f p)`. Once the computation for the `Promise` is complete, it can be written to with an `Either f p` value, i.e. `Left` reason for a failure or `Right` result in the case of success. `newPromise` will also need to fork a thread that will run the executor and set up communication so that the final `Promise` object will be updated with the results once they are available. In total, we need to: create an `MVar` which we'll call `state`, then fork a thread that calls the executor, passing it callback functions that write the results to `state`, and finally, return `state` as a `Promise` value.

```
newPromise :: ((p -> IO ()) -> (f -> IO ())) -> IO (Promise f p)
newPromise k = do
  state <- newEmptyMVar
  forkIO $ k (putMVar state . Right) (putMVar state . Left)
  return (Pending state)
```

Since the constructor here is used to create Promises that are in the *pending* state, we'll call it Pending. We could, in principle, use this same constructor to build Promise values that we know have already succeeded or failed. To get a promise that always succeeds with a value of *s*, say, simply call `newPromise` with an executor that immediately calls `successFunc`, like so:

```
newPromise (\ succeed fail -> succeed s)
```

This is inefficient, though, because it spawns an entire new thread in order to do absolutely nothing with it. Instead, it is easy enough to define a constructor that marks a value as known to be the result of a successful computation (and a parallel one declaring a value to be the known reason for a failed computation). These correspond to the promise being in the state *fulfilled* or *rejected*, respectively, so we will use those terms as the names the constructors. At this point, the Promise type has the following form [(in GADT syntax)]:

```
data Promise :: * -> * -> * where
  Pending :: MVar (Either f p) -> Promise f p
  Fulfilled :: p -> Promise f p
  Rejected :: f -> Promise f p
```

[side note: could use `Void` as `?` instead of `()` - this would cause the compiler to check that at least one of the callbacks is used - reworked into `Token` type with non exported constructor; maybe provide `hangForever :: Token` (or `IO Token`) so it can be used but can't be accidental?]

[then and catch] Now that we can create Promise values, the next step is to allow them to chain together. Javascript's `Promise.then()` is used to set a handler function to run after a promise completes. Specifically, `p1.then(f)` results in a new promise that will wait for the Promise `p1` to complete. If `p1` succeeds and resolves to a value *v*, it will then call `f(v)`. The result of running the callback should be another Promise, `p2`; when it settles, the new Promise will also settle, to the same state and value. [JS also allows the callback to return a non-Promise value, in which case `p1.then(f)` resolves to that value as soon as it's computed. We won't implement this functionality directly (allowing different argument types would not work in Haskell's type system unless we made separate then functions for the two variants). However, we get to the same result by enclosing the value we would like to return in an always-successful Promise. Once we define a monad instance for Promise *f*, we can even do so by writing `return v` where *v* is the value for the final promise to resolve to, which should look familiar to anyone used to the Javascript syntax!] In our system in Haskell, `pThen` accepts `pr`, a Promise *f p* along with a callback that expects a value type *p*, the type contained in a successful Promise *f p*. `pThen` will return a Promise (in `IO` because [blah blah asynchronous], which must have the same failure type as `pr` because if `pr` is `Rejected`, the result will be as well, with the same value. The result type can have a different success type, though, so it's overall type is `IO (Promise f p')`. The callback returns a new Promise in `IO`, which must match `pThen`'s return type, so in total

```
pThen :: Promise f p
      -> (p -> IO (Promise f p'))
      -> IO (Promise f p')
```

[implementation without `runPromise`, for only the Pending, Fulfilled, Rejected constructors.] [Note that the type signature for `pThen` looks extremely similar to the type `(>=)` would have if it were to be specialized to `Promise f ((>=) :: Promise f a -> (a -> Promise f a))`. The difference is that `pThen` is entangled in the `IO` monad.] `Promise.catch()` works the same way as `.then()` except that the handler is set to run only if and when the Promise it is being chained to fails, rather than when it succeeds.

[`runPromise` as helper function]

[Functor, Applicative, Monad instances; addition to the type so they don't need to be in `IO`]

The Javascript standard library has several ways to combine promises in parallel in addition to the sequential combination provided by `then` and `catch`.

[first describe implementation for `pRace2` - it's simpler] [JS provides `Promise.race(iterable)`], which runs all of the input promises simultaneously in different threads, settling with the result of whichever completes first. In our system this should have type signature `pRace :: [Promise f p] -> IO (Promise f p)`. To implement this function, let's begin with a binary variant that works for exactly two promises. `pRace2 :: Promise f p -> Promise f p -> IO (Promise f p)`. [similar to `amb` from [cite Push-Pull FRP]] We can use an `MVar` to accept a result from the first thread to finish. Since we must differentiate between whether the result is a success or failure, we want the `MVar` to hold an `Either f p`. We create an empty `MVar`, then fork off a pair of threads, each of which runs one of the input promises and writes the result to the `MVar`. Next, `takeMVar` waits for either thread to finish and give it a result, after which we can kill both threads since they are no longer needed. [insert `pRace2` code here]

The *n*-ary version of `pRace` operates by a sort of monadic fold over the list of input promises: we `pRace2` the first promise in the list against the result of `pRacing` the rest of the list, with the result that we will settle to whichever out of any of the inputs

settles first. The Javascript standard specifies that `race()` on an empty iterable returns a forever-pending promise that never resolves or rejects. This is convenient for our implementation because such a promise is the identity for `pRace2` so we can use it directly as the base case to our fold. We can generate an eternally pending promise by passing `newPromise` a function that fails to call either the success or failure handle, like so: `newPromise (\s f -> return ())`, so the final `pRace` function is as follows: [...]

[implementation of JS's `Promise.any(iterable)`] Javascript's promise API also provides `.any(iterable)` which combines any number of promises by executing each simultaneously. The result is a promise that immediately resolves to the value of the first input promise to successfully complete. If all of the given promises fail, it gives a list of every failure value. To implement this, let's again start with a binary version that combines exactly two promises in this way. [type signature `pAny2 :: Promise f p -> Promise f' p -> IO (Promise (f, f') p)`] [Note that this type signature is slightly more general than will be allowed by the n -ary version; in particular, the failure types of the two Promises can be different here, where in `pAny` they will need to be the same so they can be contained in the same Haskell list.] We still need an `MVar` to store the value of a success from either promise A or promise B, but dealing with a failure is somewhat more complicated since one failure isn't enough to end the computation, but we still need to track it so that we know to end if both branches end in failure. [need communication between the forked threads that doesn't interfere with the `MVar` holding successful results, => second `MVar` that the main thread doesn't touch at all. One fork writes to the error `MVar`, while the other waits to read from it after completion.]

[`pAll2` and `pAll` are dual to `pAny2` and `pAny`; we can implement by using `PromiseInvert` to switch the true and false cases of the input promises, then switching back after running them through the dual function.]

5 Comparison with Existing Concurrency Frameworks

[Compare to push-pull `frp`] [locks]

6 Future Work

[decouple Promise monad from IO ?]
